We present results of a study of neutrino oscillation based on a 766 ton-year exposure of KamLAND to reactor anti-neutrinos. We observe 258  $\overline{\nu}_e$  candidate events with energies above 3.4 MeV compared to 365.2 events expected in the absence of neutrino oscillation. Accounting for 17.8 expected background events, the statistical significance for reactor  $\overline{\nu}_e$  disappearance is 99.998%. The observed energy spectrum disagrees with the expected spectral shape in the absence of neutrino oscillation at 99.6% significance and prefers the distortion expected from  $\overline{\nu}_e$  oscillation effects. A two-neutrino oscillation analysis of the KamLAND data gives  $\Delta m^2 = 7.9^{+0.6}_{-0.5} \times 10^{-5} \, \mathrm{eV}^2$ . A global analysis of data from KamLAND and solar neutrino experiments yields  $\Delta m^2 = 7.9^{+0.6}_{-0.5} \times 10^{-5} \, \mathrm{eV}^2$  and  $\tan^2 \theta = 0.40^{+0.10}_{-0.07}$ , the most precise determination to date.

PACS numbers: 14.60.Pq, 26.65.+t, 28.50.Hw

The first measurement of reactor anti-neutrino disappearance by KamLAND [1] suggested that solar neutrino flavor transformation through the Mikheyev-Smirnov-Wolfenstein (MSW) [2] matter effect has a direct correspondence to antineutrino oscillation in vacuum. Assuming CPT invariance, KamLAND and solar-neutrino experiments have restricted the solar oscillation parameters, eliminating all but the large-mixing-angle (LMA-MSW) solution. This Letter reports more stringent constraints on neutrino oscillation parameters from KamLAND based on a three times longer exposure and a 33% increase in the usable fiducial volume. Large variations in the reactor power production in Japan in 2003 allowed us to study the  $\overline{\nu}_e$  flux dependence. The first evidence for spectral distortion in the  $\overline{\nu}_e$  spectrum is provided here; spectral

distortion is direct evidence of an oscillation effect.

KamLAND consists of 1 kton of ultra-pure liquid scintillator (LS) contained in a 13-m-diameter transparent nylon-based balloon suspended in non-scintillating oil. The balloon is surrounded by 1879 photomultiplier tubes (PMTs) mounted on the inner surface of an 18-m-diameter spherical stainless-steel vessel. Electron anti-neutrinos are detected via inverse  $\beta$ -decay,  $\overline{\nu}_e+p\to e^++n$ , with a 1.8 MeV  $\overline{\nu}_e$  energy threshold. The prompt scintillation light from the  $e^+$  gives an estimate of the incident  $\overline{\nu}_e$  energy,  $E_{\overline{\nu}_e}=E_{\rm prompt}+\overline{E}_n+0.8$  MeV, where  $E_{\rm prompt}$  is the prompt event energy including the positron kinetic energy and the annihilation energy, and  $\overline{E}_n$  is the average neutron recoil energy. The  $\sim 200~\mu s$  delayed 2.2 MeV  $\gamma$  ray from neutron capture on hydrogen is

a powerful tool for reducing background. On average, neutrons are captured within 9 cm and the spatial correlation between prompt and delayed signals is dominated by the vertex position resolution. A 3.2 kton water-Cherenkov detector surrounds the containment sphere, absorbing  $\gamma$  rays and neutrons from the surrounding rock and tagging cosmic-ray muons. This outer detector (OD) is over 92% efficient for muons passing through the fiducial volume.

KamLAND is surrounded by 53 Japanese power reactor units. The reactor operation data, including thermal power generation, fuel burn up, exchange and enrichment records, are provided by all Japanese power reactors and are used to calculate fission rates of each isotope. The averaged relative fission yields for the run period were  $^{235}\text{U}:^{239}\text{Pu}:^{241}\text{Pu}=0.563:0.079:0.301:0.057$ . The expected  $\overline{\nu}_e$  flux is calculated using fission rates and  $\overline{\nu}_e$  spectra; the spectra are from Ref. [3]. The  $\overline{\nu}_e$  contribution from Japanese research reactors and all reactors outside of Japan is 4.5%. We assume that these reactors have the same average fuel composition as the Japanese power reactors. The total integrated thermal power flux over the detector livetime was 701 Joule/cm².

We report on data collected between March 9, 2002 and January 11, 2004, including re-analysis of the data used in Ref. [1]. The central detector PMT array was upgraded on February 27, 2003 by commissioning 554 20-inch PMTs, increasing the photo-cathode coverage from 22% to 34% and improving the energy resolution from  $7.3\%/\sqrt{E(\text{MeV})}$  to  $6.2\%/\sqrt{E(\text{MeV})}$ . The trigger threshold of 200 hit 17-inch PMTs corresponds to about 0.7 MeV at the detector center and has an efficiency close to 100%. We use a prompt event energy analysis threshold of 2.6 MeV to avoid backgrounds including the effect of anti-neutrinos from uranium and thorium decaying in the Earth (geo-neutrinos).

The location of interactions inside the detector is determined from PMT hit timing; the energy is obtained from the number of observed photo-electrons after correcting for position and gain variations. Position and time dependence of the energy estimation are monitored periodically with  $\gamma$ -ray and neutron sources along the central vertical axis (z-axis) of the scintillator volume. Trace radio-isotopes on the balloon and in the scintillator are also exploited. The systematic uncertainty in the energy scale at the 2.6 MeV prompt event energy ( $E_{\overline{\nu}_e} \simeq 3.4 \, \text{MeV}$ ) analysis threshold is 2.0%, corresponding to a 2.3% uncertainty in the number of events in an unoscillated reactor  $\overline{\nu}_e$  spectrum.

The radial fiducial volume cut is relaxed from 5 m [1] to 5.5 m in the present analysis, expanding the fiducial mass to 543.7 tons (4.61×10³¹ free target protons). The radial positions of the prompt and delayed event are both required to be less than 5.5 m. The 1.2 m cylindrical cut along the z-axis previously used to exclude low energy backgrounds from thermometers is not applied. The event selection cuts for the time difference ( $\Delta T$ ) and position difference ( $\Delta R$ ) between the positron and delayed neutron are 0.5  $\mu$ s <  $\Delta T$  < 1000  $\mu$ s and  $\Delta R$  < 2 m, respectively. The event energies are re-

quired to be 1.8 MeV  $< E_{\rm delayed} <$  2.6 MeV and 2.6 MeV  $< E_{\rm prompt} <$  8.5 MeV. The efficiency of all cuts is (89.8  $\pm$  1.5)%.

The total volume of the liquid scintillator is  $1171 \pm 25 \,\mathrm{m}^3$ , as measured by flow meters during detector filling. The nominal 5.5-m-radius fiducial volume  $(\frac{4}{3}\pi R^3)$  corresponds to  $0.595 \pm 0.013$  of the total LS volume. The effective fiducial volume is defined by the cuts on the radial positions of the reconstructed event vertices. At present, only z-axis calibrations are available, so we assess the systematic uncertainty in the total fiducial volume by studying uniformly-distributed muon spallation products, identified as delayed coincidences following muons. We measure the position distribution of the  $\beta$ -decays of  $^{12}\text{B}$  (Q = 13.4 MeV,  $au_{1/2}$  = 20.2 ms) and  $^{12}\text{N}$  $(Q=17.3\,\mathrm{MeV},\ \tau_{1/2}=11.0\,\mathrm{ms}),\ \mathrm{which}$  are produced at the rate of about 60 <sup>1/2</sup>B/<sup>1/2</sup>N events/kton-day. Fits to the energy distribution of these events indicate that the sample is mostly  $^{12}$ B; the relative contribution of  $^{12}$ N is only  $\sim 1\%$ . The number of <sup>12</sup>B/<sup>12</sup>N events reconstructed in the fiducial volume compared to the total number in the entire LS volume is  $0.607 \pm 0.006(\text{stat}) \pm 0.006(\text{syst})$ , where the systematic error arises from events near the balloon surface that deposit a fraction of their energy outside the LS. As a consistency check, in a similar study of spallation neutrons, which we identify via the 2.2 MeV capture  $\gamma$  ray, we find the ratio  $0.587 \pm 0.013$ (stat).

The  $^{12}\mathrm{B}/^{12}\mathrm{N}$  events typically have higher energy than  $\overline{\nu}_e$  candidates, so an additional systematic error accounts for possible dependence of effective fiducial volume on energy. We constrain the variation to 2.7% by comparing the prompt and delayed event positions of delayed-neutron  $\beta$ -decays of  $^9\mathrm{Li}~(Q=13.6\,\mathrm{MeV},~\tau_{1/2}=178\,\mathrm{ms})$  and  $^8\mathrm{He}~(Q=10.7\,\mathrm{MeV},~\tau_{1/2}=119\,\mathrm{ms})$ . The observed capture distance variation is a measure of the energy uniformity of the vertex finding algorithm. Combining the errors from the LS volume measurements, the  $^{12}\mathrm{B}/^{12}\mathrm{N}~$  volume ratio calibration, and the constraints on energy dependence, we obtain a 4.7% systematic error on the fiducial volume.

The rate of accidental coincidences increases in the outer region of the fiducial volume, since most background sources are external to the liquid scintillator. This background is estimated with a 10 ms to 20 s delayed-coincidence window and by pairing random singles events. These consistent methods predict  $2.69 \pm 0.02$  events above the 2.6 MeV threshold.

Above  $2.6\,\mathrm{MeV}$ , neutrons and long-lived delayed-neutron  $\beta$ -emitters are sources of correlated backgrounds. The  $\sim\!3000$  spallation-produced neutrons per kton-day are effectively eliminated with a 2 ms veto of the entire detector following a detected muon. The remaining fast neutrons come from muons missed by the OD or interacting in the rock just outside it. This background is reduced significantly by the OD and several layers of absorbers: the OD itself, the 2.5 m of non-scintillating oil surrounding the LS, and the 1 m of LS outside the fiducial volume. We estimate this background contributes fewer than 0.89 events to the data sample.

The uncorrelated background from <sup>12</sup>B/<sup>12</sup>N spallation products is effectively suppressed by the delayed-coincidence

TABLE I: Estimated systematic uncertainties (%).

·			
Fiducial Volume	4.7	Reactor power	2.1
Energy threshold	2.3	Fuel composition	1.0
Efficiency of cuts	1.6	$\overline{\nu}_e$ spectra [3]	2.5
Livetime	0.06	Cross section [5]	0.2
Total systematic uncertainty			6.5

A third source of correlated background comes indirectly from the  $\alpha$  decays of the radon daughter <sup>210</sup>Po in the liquid scintillator. The signal of the 5.3 MeV  $\alpha$ -particle is quenched below the threshold, but the secondary reaction  ${}^{13}\text{C}(\alpha,n){}^{16}\text{O}$ produces events above 2.6 MeV. Special runs to observe the decay of  $^{210}$ Po establish that there were  $(1.47\pm0.20)\times10^9~\alpha$ decays during the livetime of data taking. Using the  $^{13}$ C( $\alpha$ ,n) reaction cross sections from Ref. [4], Monte Carlo simulations and detailed studies of quenching effects to convert the outgoing neutron energy spectrum into a visible energy spectrum, we expect  $10.3 \pm 7.1$  events above 2.6 MeV. The spectrum is concentrated around 6 MeV, from decays of levels in <sup>16</sup>O, and 4.4 MeV, from  $\gamma$  decays following neutron inelastic scattering on <sup>12</sup>C. The observed energy from neutron-proton elastic scattering is mostly quenched below 2.6 MeV. This  $\alpha$ -induced background was not considered in Ref. [1] and would have contributed  $1.9 \pm 1.3$  additional background events ( $2.8 \pm 1.7$ total background events). The total background to the  $\overline{\nu}_e$ signal above 2.6 MeV in the present analysis is  $17.8 \pm 7.3$ events, where the bound on the fast neutron background is accounted for in the uncertainty.

In the absence of anti-neutrino disappearance, we expect to observe  $365.2 \pm 23.7 (\text{syst}) \ \overline{\nu}_e$  events above  $2.6 \, \text{MeV}$ , where the systematic uncertainty is detailed in Table I. We observe  $258 \, \text{events}$ , confirming  $\overline{\nu}_e$  disappearance at the 99.998% significance level. The average  $\overline{\nu}_e$  survival probability is  $0.658 \pm 0.044 (\text{stat}) \pm 0.047 (\text{syst})$ , where the background error has been included in the systematic uncertainty. The effective baseline varies with power output of the reactor sources involved, so the survival probabilities for different periods are not directly comparable. Applying the new analysis on the previously reported data (March 2002 to October 2002) [1] gives  $0.601 \pm 0.069 (\text{stat}) \pm 0.042 (\text{syst})$ , in agree-

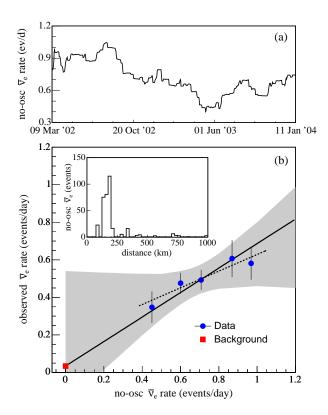

FIG. 1: (a) Estimated time variation of the reactor  $\overline{\nu}_e$  flux at KamLAND assuming no anti-neutrino oscillation. (b) Observed  $\overline{\nu}_e$  event rate versus no-oscillation reactor  $\overline{\nu}_e$  flux. Data points correspond to intervals of approximately equal  $\overline{\nu}_e$  flux. The dashed line is a fit, the 90% C.L. is shown in gray. The solid line is a fit constrained to the expected background. The reactor distance distribution for  $\overline{\nu}_e$  events in the absence of oscillations is shown in the inset.

ment with  $0.589 \pm 0.085(\text{stat}) \pm 0.042(\text{syst})$ , after correction for the  $(\alpha, n)$  background.

After September 2002, a number of Japanese nuclear reactors were off, as indicated in Fig. 1a. This decreased the expected no-oscillation  $\overline{\nu}_e$  flux by more than a factor of two. In Fig. 1b the signal counts are plotted in bins of approximately equal  $\overline{\nu}_e$  flux corresponding to total reactor power. For  $\Delta m^2$  and  $\tan^2 \theta$  determined below and the known distributions of reactor power level and distance, the expected oscillated  $\overline{\nu}_e$  rate is well approximated by a straight line. The slope can be interpreted as the reactor-correlated signal and the intercept as the reactor-independent constant background rate. Fig. 1b shows the linear fit and its 90% C.L. region. The intercept is consistent with known backgrounds, but substantially larger backgrounds cannot be excluded; hence this fit does not usefully constrain speculative sources of anti-neutrinos such as a nuclear reactor at the Earth's core [6]. The predicted KamLAND rate for typical 3 TW geo-reactor scenarios is comparable to the expected  $17.8 \pm 7.3$  event background and would have minimal impact on the analysis of the reactor power dependence signal. In the following we consider contributions only from known anti-neutrino sources.

Fig. 2a shows the correlation of the prompt and delayed

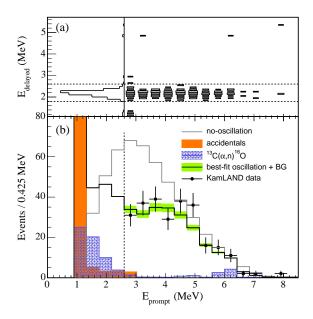

FIG. 2: (a) The correlation between the prompt and delayed event energies after cuts. The three events with  $E_{\rm delayed} \sim 5\,{\rm MeV}$  are consistent with neutron capture on carbon. (b) Prompt event energy spectrum of  $\overline{\nu}_e$  candidate events with associated background spectra. The shaded band indicates the systematic error in the best-fit reactor spectrum above 2.6 MeV.

event energy after all selection cuts except for the  $E_{\rm delayed}$ cut. The prompt energy spectrum above 2.6 MeV is shown in Fig. 2b. The data evaluation method with an unbinned maximum likelihood fit to two-flavor neutrino oscillation is similar to the method used previously [1]. In the present analysis, we account for the  ${}^{9}\text{Li}$ , accidental and the  ${}^{13}\text{C}(\alpha, n){}^{16}\text{O}$ background rates. For the  $(\alpha,n)$  background, the contribution around 6 MeV is allowed to float because of uncertainty in the cross section, while the contributions around 2.6 MeV and 4.4 MeV are constrained to within 32% of the estimated rate. We allow for a 10% energy scale uncertainty for the 2.6 MeV contribution due to neutron quenching uncertainty. The best-fit spectrum together with the backgrounds is shown in Fig. 2b; the best-fit for the rate-and-shape analysis is  $\Delta m^2 = 7.9^{+0.6}_{-0.5} \times 10^{-5} \, \mathrm{eV^2}$  and  $\tan^2 \theta = 0.46$ , with a large uncertainty on  $\tan^2 \theta$ . A shape-only analysis gives  $\Delta m^2 = (8.0 \pm 0.5) \times 10^{-5} \,\text{eV}^2$  and  $\tan^2 \theta = 0.76$ .

Taking account of the backgrounds, the Baker-Cousins  $\chi^2$  for the best-fit is 13.1 (11 DOF). To test the goodness-of-fit we follow the statistical techniques in Ref. [7]. First, the data are fit to a hypothesis to find the best-fit parameters. Next, we bin the energy spectrum of the data into 20 equal-probability bins and calculate the Pearson  $\chi^2$  statistic  $(\chi^2_p)$  for the data. Based on the particular hypothesis 10,000 spectra were generated using the parameters obtained from the data and  $\chi^2_p$  was determined for each spectrum. The confidence level of the data is the fraction of simulated spectra with a higher  $\chi^2_p$ . For the best-fit oscillation parameters and the *a priori* choice of 20 bins, the goodness-of-fit is 11.1%

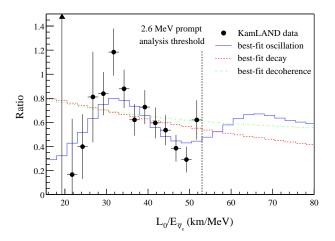

FIG. 3: Ratio of the observed  $\overline{\nu}_e$  spectrum to the expectation for no-oscillation versus  $L_0/E$ . The curves show the expectation for the best-fit oscillation, best-fit decay and best-fit decoherence models taking into account the individual time-dependent flux variations of all reactors and detector effects. The data points and models are plotted with  $L_0$ =180 km, as if all anti-neutrinos detected in KamLAND were due to a single reactor at this distance.

with  $\chi_p^2/\text{DOF} = 24.2/17$ . The goodness-of-fit of the scaled no-oscillation spectrum where the normalization was fit to the data is 0.4% ( $\chi_p^2/\text{DOF} = 37.3/18$ ). We note that the  $\chi_p^2$  and goodness-of-fit results are sensitive to the choice of binning.

To illustrate oscillatory behavior of the data, we plot in Fig. 3 the L<sub>0</sub>/E distribution, where the data and the bestfit spectra are divided by the expected no-oscillation spectrum. Two alternative hypotheses for neutrino disappearance, neutrino decay [8] and decoherence [9], give different L<sub>0</sub>/E dependences. As in the oscillation analysis, we survey the parameter spaces and find the best-fit points at  $(\sin^2 \theta, m/c\tau) = (1.0, 0.011 \text{ MeV/km})$  for decay and  $(\sin^2 2\theta, \gamma^0) = (1.0, 0.030 \,\text{MeV/km})$  for decoherence, using the notation of the references. Applying the goodness-of-fit procedure described above, we find that decay has a goodnessof-fit of only 0.7% ( $\chi_p^2/DOF = 35.8/17$ ), while decoherence has a goodness-of-fit of 1.8% ( $\chi_p^2/DOF = 32.2/17$ ). We note that, while the present best-fit neutrino decay point has already been ruled out by solar neutrino data [10] and observation of SN1987A, the decay model is used here as an example of a scenario resulting in a  $\overline{\nu}_e$  deficit. If we do not assume CPT invariance and allow the range  $0.5 < \sin^2 \theta < 0.75$ , then the decay scenario considered here can avoid conflict with solar neutrino [10] and SN1987A data [11].

The allowed region contours in  $\Delta m^2$ -tan²  $\theta$  parameter space derived from the  $\Delta \chi^2$  values (e.g.,  $\Delta \chi^2 < 5.99$  for 95% C.L.) are shown in Fig. 4a. The best-fit point is in the region commonly characterized as LMA I. Maximal mixing for values of  $\Delta m^2$  consistent with LMA I is allowed at the 62.1% C.L. Due to distortions in the spectrum, the LMA II region (at  $\Delta m^2 \sim 2 \times 10^{-4} \, \mathrm{eV}^2$ ) is disfavored at the 98.0% C.L., as are larger values of  $\Delta m^2$  previously allowed by KamLAND. The allowed region at lower  $\Delta m^2$  is disfavored at the 97.5%

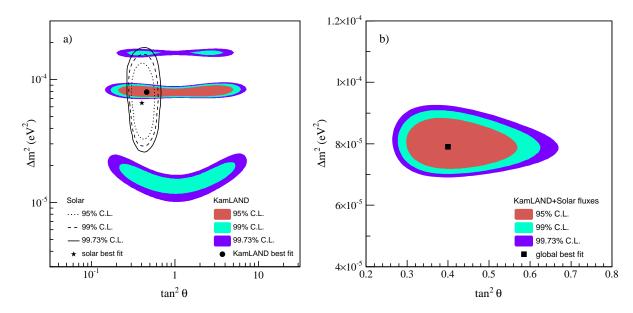

FIG. 4: (a) Neutrino oscillation parameter allowed region from KamLAND anti-neutrino data (shaded regions) and solar neutrino experiments (lines) [12]. (b) Result of a combined two-neutrino oscillation analysis of KamLAND and the observed solar neutrino fluxes under the assumption of CPT invariance. The fit gives  $\Delta m^2 = 7.9^{+0.6}_{-0.5} \times 10^{-5} \, \text{eV}^2$  and  $\tan^2 \theta = 0.40^{+0.10}_{-0.07}$  including the allowed 1-sigma parameter range.

C.L., but this region is not consistent with the LMA region determined from solar neutrino experiments assuming CPT invariance.

A two-flavor analysis of the KamLAND data and the observed solar neutrino fluxes [13], with the assumption of CPT invariance, restricts the allowed  $\Delta m^2\text{-}\tan^2\theta$  parameters in Fig. 4b. The sensitivity in  $\Delta m^2$  is dominated by the observed distortion in the KamLAND spectrum, while solar neutrino data provide the best constraint on  $\theta$ . The combined analysis gives  $\Delta m^2 = 7.9^{+0.6}_{-0.5} \times 10^{-5} \, \mathrm{eV}^2$  and  $\tan^2\theta = 0.40^{+0.10}_{-0.07}$ .

The conclusion that the LMA II region is excluded is strengthened by the present result. The observed distortion of the spectral shape supports the conclusion that the observation of reactor  $\overline{\nu}_e$  disappearance is due to neutrino oscillation. Statistical uncertainties in the KamLAND data are now on the same level as systematic uncertainties. Current efforts to perform full-volume source calibrations and a reevaluation of reactor power uncertainties should reduce the systematic uncertainties.

The KamLAND experiment is supported by the COE program under grant 09CE2003 of the Japanese Ministry of Education, Culture, Sports, Science and Technology, and under the United States Department of Energy grant DEFG03-00ER41138. The reactor data are provided by courtesy of the following electric associations in Japan: Hokkaido, Tohoku, Tokyo, Hokuriku, Chubu, Kansai, Chugoku, Shikoku and Kyushu Electric Power Companies, Japan Atomic Power Co. and Japan Nuclear Cycle Development Institute. The Kamioka Mining and Smelting Company has provided service for activities in the mine.
